The effect of partial vacuum on the chemical preparation of the root canal system:

The Sleiman sequence

Authors: Prof. Philippe Sleiman & Dr Alfredo Iandolo, Lebanon/Italy

Introduction

From the early 20th century, when Walter Hess and Ernest Zürcher1 demonstrated root canal anatomy with an unprecedented visual clarity, its complexity has fascinated researchers armed with ever better imaging tools—from blue dyes to CT, from CBCT to confocal microscopy, from clear tooth preparations to micro-CT2–4, to name just a few. Thanks to rigorous research and discussion, the diverse intricacy of root canal morphology is well understood and accepted today. However, the question of how to best prepare this space to restore homeostasis remains open to debate, which is conducted both in the scientific and, unfortunately, commercial domains. Our task as scholars and clinicians is to investigate which approaches would be practical and applicable to bring teeth and periodontium back to health in accordance with evidence-based endodontics and principles of minimally-invasive dentistry.

As yet another array of new file systems are launched in the market, we seem to share an understanding that files do not have the ability to clean root canal space, only preparing, i.e. shaping it, while it is the irrigation process that provides a level of cleanliness that can, hopefully, create conditions for the body to heal. Thus, given that the shaping is acceptable (i.e. the files used remove the bulk of the pulp and/or infected dentine without blocking the system with debris as well as maintain the original shape of the canal without any micro-crack formation), it is the chemical preparation that is responsible for treating the system in all its complexity.

For a long time, irrigation remained a somewhat mystical part of the process, with a general agreement that a good rinse is necessary, but without a standardised sequence of irrigation. While various tools for irrigation and activation of solutions were studied extensively, the first sequence was suggested only in 2005,5, 6 and it made clinicians aware that alternating solutions could be as beneficial as the use of negative pressure in order to achieve a clean root canal space and diminish postoperative pain.

Below you will find descriptions and outcomes of several studies that led to a suggested protocol of irrigation that is presented in the conclusion of the present publication.
Investigating irrigation today

The fact that during root canal shaping the system may get blocked by debris led to the question of how to best conduct the chemical preparation so that the dentinal tubules remain open to allow for a better cleaning and, consequently, sealing of the system. Drawing from clinical experience and improved outcomes, Jaramillo et al. have formulated an experimental irrigation sequence based on Sleiman's 2005 suggestions, and added a negative pressure device to see if it may have added benefits.  

Scanning electron microscopy used to evaluate the cleanliness of dentinal tubules at three different levels of the canals demonstrated that our experimental sequence—alternating the use of 6% NaOCl and 17% EDTA with water in between—had shown a significantly better ability to keep the entrances of dentinal tubules open and avoid the blockage of dentinal tubules by the smear layer and debris during the cleaning and shaping procedure compared with the use of 6% NaOCl or 17% EDTA alone. The results emphasised the importance of the early use of 17% EDTA and not only as a final rinse.

Another finding of the study that echoed positive clinical outcomes related to the use of negative pressure in combination with the experimental irrigation sequence; the irrigation protocol that included both the Sleiman sequence (alternating between sodium hypochlorite, water, and EDTA) and a negative pressure irrigation device was proven to be the most efficient in opening dentinal tubules and maintaining them open. It may be posited that the negative pressure allows for a formation of a temporary partial vacuum force, which first draws the liquids from the

Fig. 1b: Sleiman-Iandolo testing. Demonstrating the airlock eliminated with the use of the negative pressure irrigation system (NB: other means such as further PUI or use of lateral-vented needle were not helpful in overcoming the vapor lock—once produced, the gas bubble remained in place).

Fig. 2a: Sleiman-Iandolo testing. Freshly extracted premolar dyed with methylene blue in a centrifuge. Note the deep penetration of the dye, especially in the coronal part.

technique  root canal preparation

access cavity into the root canal system and then
suctions them out of the system.

Using the macro- and the micro-cannulas of the
negative pressure irrigation unit in, correspondingly,
the coronal-middle and apical parts of the root canal
system, leads to the creation of a vacuum, or a partial
vacuum, to be more specific, inside the root canal
space. Though its main role is to attract solutions
deeper and deeper into the system and safely remove
them from within, the partial vacuum created by the
negative pressure has a number of other important
benefits as Sleiman-Iandolo testing has shown.

First of all, it can eliminate the airlock (better known
in endodontics as vapor lock) inevitably resulting
from bubbly chemical reactions between irrigating
solutions and the content of the root canal space in-
side the main canal—mainly in the apical part—as well
as inside lateral canals and dentinal tubules and pre-
venting the irrigants from reaching these areas and
performing their best (Figs. 1a & b). Secondly, once the
airlock is eliminated, the partial vacuum force helps in
distributing irrigants into the totality of the root canal
system, including the depth of the dentinal tubules.
Thirdly, negative pressure irrigation allows for intro-
ducing a significantly larger volume of irrigating
solutions over a shorter period of time, increasing the
efficiency and decreasing the length of the procedure.
These unique properties result in a faster and better
chemical preparation of the entire internal space.

Sleiman–Iandolo testing used freshly extracted
premolars, removed due to periodontal pathology,
impregnated with methylene blue dye in a centri-
fuge; this resulted in pushing the dye deeply into the
dentinal tubules (Fig. 2a). To compare commonly
used irrigant delivery techniques, a negative pressure
irrigation unit was used (EndoVac) as well as a later-
vented needle, manual activation of the solution,
and passive ultrasonic irrigation in combination with
the Sleiman irrigation sequence. EndoVac + Sleiman
sequence was shown to be the only approach that
allowed for a complete removal of the methylene
blue dye from the entire root canal system and den-
tinal tubules over the total time of 25 minutes, while
the other approaches failed to achieve a completely
clean system (Figs. 2b & c).

The Sleiman sequence goes beyond using water as
an intermediate between the two alternating solu-
tions and as the final irrigant (water cooled to be-
tween 2.5°C and 4°C and used for postoperative pain
control or in a cryotherapy modality also suggested
by Sleiman8 and investigated by Vera et al.9)—it
also stipulates that when using the macro- or the
micro-cannula of the negative pressure irrigation
unit for chemical preparation, every five seconds a
two-to-three-second pause should be made when
no irrigant is added. It is during this pause that the
partial vacuum is created by the cannula, which will

(left) and a negative pressure irrigation
unit used at the intervals suggested as
part of the Sleiman sequence (right).
Note the extreme cleanliness of the
deepest recesses of the dentinal
tubules in the image on the right.

Fig. 3: A necrotic/infected case: Lower
premolar of the patient complaining of
dull and pulsating pain. The infection
was not limited to the apical part, but
was also located in the lateral mid-root
section. Postoperative X-ray shows a
3-D sealing of the apical area with its
anastomosis and of the lateral and
accessory canals in mid root.

Fig. 4: Complexity of the apical area
manifests itself after it was treated
chemically, dried, and sealed by way of
the warm vertical technique.

Fig. 5: The case was referred for
retreatment due to the failure of the
previous root canal therapy. Following
the shaping (TF-adaptive) and cleaning
(Sleiman protocol), and upon the
challenging but successful search for
the distal canal, a 3-D obturation was
performed, which allows showing the
isthmus between the mesial and distal
canals as well as a very coronally
located lateral canal in the palatal root.
draw out all the fluids, residues and gases from all the root canal system. Once the system has been drained, the partial vacuum established inside the root canal system in its entirety can attract a fresh portion of irrigant for a faster and cleaner preparation of the root canal system.

Clinical cases

In the images above, we present some of the typical cases demonstrating the cleanliness of the root canal system achieved as shown by the lateral and/or accessory canals visualised upon 3D warm vertical condensation (Figs. 3–6).

The case of a failing root canal treatment with apical infection and an internal resorption in the apical area was referred to us (Fig. 7). After removing the previous filling, chemical preparation was performed, with the help of the partial vacuum inside the system the chemicals were able to clean the resorption area without an aggressive effect on the periodontal ligament; this has led to a truly three-dimensional obturation. The 4-month follow-up image (Fig. 8) confirms a fast healing of both the apical area and the area of the resorption lesion.

Conclusions

Realising that a 100% disinfection of the root canal space remains unattainable, we continue to strive for perfection in our attempts to develop viable clinical protocols that would allow to lower the inflammatory and/or bacterial load so that our patients’ bodies can heal. Based on the supporting research and testing as well as on a history of sustainably high treatment outcomes for both primary endodontic treatment and retreatment of vital and non-vital teeth, we would like to propose our irrigation protocol as a fast, safe, and, most importantly, evidence-based technique of chemical preparation.

The Sleiman irrigation protocol requires 6% (or 5.25%, if the 6% concentration is not available) NaOCl, 17% EDTA, distilled water or normal saline. For the best results it is recommended to use a negative pressure irrigation unit to introduce and remove the solutions in order to benefit from the partial vacuum force; however, it must be said that using other introduction techniques in combination with the Sleiman sequence of irrigants will also improve chemical preparation results and lead to a cleaner root canal space.

- Access cavity; manual files to locate orifices; manual files for initial scouting—NaOCl
- H₂O
- Machine files for root canal preparation—EDTA
- H₂O
- In between machine files—NaOCl
- H₂O (cold for cryotherapy)
- Drying the root canal system—EndoVac

The whole irrigation procedure should follow the ‘5 sec introducing solution + 3 sec pause’ guideline to achieve the best effect of the partial vacuum.
