Case Report Maxillary Implant

By Stavros Mastronikolas
D.D.S., M.Sc. Periodontist
(Dubai, UAE)

Extraction, site preservation and delayed placement of maxillary implant using the bone added osteotome sinus floor elevation technique.

Initial Presentation
Pt is a 28 y.o. female, medically healthy, denies taking any medications, reports a heavy smoker, NKDA’s. A cone-beam computed tomographic scan was acquired pre-operatively. A prophylaxis was completed with minimal tension. Post op instructions were given.

Results
Pre-treatment the alveolar ridge dimensions of the first maxillary molar were 12mm width x 8mm height and 3 months post fixture placement the ridge dimensions were 9mm width x 7mm height. Verified with the cone-beam computerized tomographic scan a 4mm internal sinus lift was achieved using FDBA (Freeze Dried Bone Allograft) and osteotome instruments.

Conclusions
Ridge dimensions can be preserved on extracted molars with deficient alveolar architecture. Successful site preservation can favor placing fixtures flapless decreasing patients’ morbidity and chair time. Internal sinus lift with the bone added osteotome sinus floor elevation technique is a successful procedure. The FDBA placed into the maxillary sinus cavity appears to surround circumferentially the implant having intimate contact with it.

Acknowledgments
The author wants to thank Ledenet Health for providing the allograft materials used in this case report. Furthermore special thanks to Dr. Paul Rosen (www.psrperiimplant.com) for his review for this case report.

About the Author
Periodontist Dr. Stavros Mastronikolas received his dental degree at University of Illinois at Chicago. He completed his advanced training in periodontology and implantology at University of Maryland at Baltimore. He is a Diplomate of the American Board of Periodontology. At the moment Dr. Mastronikolas is working full time as a Periodontist and Implant Surgeon at Drs Nicolas and Asp (Dubai, UAE).

Stem cells in implant dentistry

By Dr. André Antonio Pelegrine, Brazil

The human body contains over 200 different types of cells, which are organised into tissues and organs that perform all the tasks required to maintain the viability of the system, including reproduction. In healthy adult tissues, the cell population size is the result of a fine balance between cell proliferation, differentiation, and death.

Following tissue injury, cell proliferation begins to repair the damage. In order to achieve this, quiescent cells (dormant cells) in the tissue become proliferative, or stem cells are activated and differentiate into the appropriate cell type needed to repair the damaged tissue. Research into stem cells seeks to understand tissue maintenance and repair in adulthood and the derivation of the significant number of cell types from human embryos.

It has long been observed that tissues can differentiate into a wide variety of cells, and in the case of blood, skin and the gastric lining the differentiated cells possess a short half-life and are incapable of renewing themselves. This has led to the idea that some tissues may be maintained by stem cells, which are defined as cells with enormous renewal capacity (self-replication) and the ability to generate daughter cells with the capacity of differentiation. Such cells, also known as adult stem cells, will only produce the appropriate cell lines for the tissues in which they reside (Fig. 1).

Not only can stem cells be isolated from both adult and embryo tissues; they can also be kept in cultures as undifferentiated cells. Embryo stem cells have the ability to produce all the differentiated cells of an adult. Their potential can therefore be extended beyond the conventional mesodermal lineage to include differentiation into liver, kidney, muscle, skin, cardiac, and nerve cells (Fig. 2).

The recognition of stem cell potential unearthed a new age in medicine: the age of regenerative medicine. It has made it possible to consider the regeneration of damaged tissue or an organ that would otherwise be lost. Because the use of embryo stem cells raises ethical issues for obvious reasons, most scientific studies focus on the applications of adult stem cells. Adult stem cells
are not considered as versatile as embryo stem cells because they are widely regarded as multipotent, that is, capable of giving rise to certain types of specific cells/tissues only, whereas the embryo stem cells can differentiate into any types of cells/tissues. Advances in scientific research have determined that some tissues have greater difficulty regenerating, such as the nervous tissue, whereas bone and blood, for instance, are considered more suitable for stem cell therapy.

In dentistry, pulp from primary teeth has been thoroughly investigated as a potential source of stem cells with promising results. However, the regeneration of an entire tooth, known as third dentition, is a highly complex process, which despite some promising results with animals remains very far from clinical applicability. The opposite has been observed in the area of jawbone regeneration, where there is a higher level of scientific evidence for its clinical applications. Currently, adult stem cells have been harvested from bone marrow and fat, among other tissues.

Bone marrow harvesting is carried out under local anaesthesia using an aspiration needle through the iliac (pelvic) bone. Other than requiring a competent doctor to perform such a task, it is not regarded as an excessively invasive or complex procedure. It is also not associated with high levels of pain.

- **Fig. 5d:** A bone graft being harvested from the angle of the leg (tibia or fibula).
- **Fig. 5e:** A bone graft from the pelvic bone (iliac).

Bone marrow is haematopoietic, that is, capable of producing all the blood cells. Since the 1950s, when Nobel Prize winner Dr. E. Donnall Thomas demonstrated the viability of bone marrow transplants in patients with leukaemia, many lives have been saved using this approach for a variety of immunological and haematopoietic illnesses. However, the bone marrow contains more than just haematopoietic stem cells (which give rise to red and white blood cells, as well as platelets, for example); it is also home to mesenchymal stem cells (which will become bone, muscle and fat tissues, for instance; Fig. 5).

Bone marrow harvesting is carried out under local anaesthesia using an aspiration needle through the iliac (pelvic) bone. Other than requiring a competent doctor to perform such a task, it is not regarded as an excessively invasive or complex procedure. It is also not associated with high levels of pain.
of discomfort either intra or post-operatively (Figs. 4a & b). Bone reconstruction is a challenge in dentistry (also in orthopaedics and oncology) because rebuilding bony defects caused by trauma, infections, tumours or dental extractions requires bone grafting. The lack of bone in the jaws may impede the placement of dental implants, thus adversely affecting patients’ quality of life. In order to remedy bone scarcity, a bone graft is conventionally harvested from the chin region or the angle of the mandible. If the amount required is too large, bone from the skull, legs or pelvis may be used. Unlike the process for harvesting bone marrow, the process involved in obtaining larger

---

In a fifth group of animals, no cell therapy method (control group) was used. The best bone regeneration results were found in the groups in which a bone marrow stem cell concentrate and a bone marrow stem cell culture were used, and the control group showed the worst results. Consequently, it was suggested that stem cells from bone marrow would be more suitable than those from fat tissue for bone reconstruction and that a simple stem cell concentrate method (which takes a few hours) would achieve similar results to those obtained using complex cell culture procedures (which take on average three to four weeks; Figs. 5a & b).

Similar studies performed in humans have corroborated the finding that bone marrow stem cells improve the repair of bony defects caused by trauma, dental extractions or tumours. The histological images below illustrate the potential of bone-sparing materials combined with stem cells for bone reconstruction (Fig. 9). It is clear that the level of mineralised tissue is significantly higher in those areas where stem cells were applied (Figs. 10a & b).
