The implant surgeon may feel a case is successful based on the criteria, but it can be seen as a failure if all of the patient’s desires are not fulfilled. It is therefore important during the initial consultation to listen to the patient and understand what he or she is hoping to achieve. Following careful clinical and radiographic evaluation, the range of options should be presented and a treatment decided upon that best suits both clinician and patient. Risks and complications can be listed and explained in a comprehensive consent form tailor-made for that patient.

Periodontal status must be measured and treated if necessary before beginning any sort of implant therapy. A clear interaction with either the hygienist or the periodontist is crucial for long-term success.

Any active decay should be noted and treated. Also check for occlusal disharmonies and decide whether to use a conformative or a re-organised approach.

The type of soft tissue around the proposed site should be noted, as this will have a significant effect on the restorative and long-term success. Smile lines, current position and colour of the teeth are all noted to determine the final desired result.

The medical history
A detailed medical history will enable assessment of any risk involved during or after the surgery. Interaction with the patient’s physician will help deal with patients with complicated medical histories, including those who are taking anticoagulants, have had major surgery or cancer treatment. These patients are suitable for surgery providing that set protocols are followed.

Current medication, such as bisphosphonates, can also affect the outcome of surgery. This is not a contraindication provided set guidelines are followed.

Periapical radiographs
Simple periapical images help to assess bone level, periapical pathology, caries and current restorative situation of teeth. This assists in deciding on prognosis and treatment for each tooth.

Calibrated ball bearings are useful to measure the height of...
Pan-oral radiographs are very useful to view overall condition of current dentition and bone level, vital structures or the level and size of maxillary sinuses.

Ridge mapping

Often, ridge width will appear insufficient for implant placement, but once a flap is raised, the true width of the bone is very narrow. This is due to the thick soft tissue above the bone ridge.

The surgeon is therefore left with the issue of grafting the narrow ridge and delaying implant placement as well as explaining extra cost and time to the patient.

CT scan

CT scans are also very useful in exploring the sinus before augmentation procedures. In a significant number of cases, maxillary sinuses have a septum that can lead to complications. Knowledge of this can help surgeons modify the design of the window needed to lift the floor of the sinus.
