The incision is made using a disposable CK2 microsurgical blade (SybronEndo). With the smaller size of this blade, accurate incisions can be made that have a cleaner cut than those of the much larger BP #15 or BP #15S blades. As the incision is being made, the operator needs to visualise the suturing process. Sometimes just a small variation in the design of the incision can make a significant difference to easier and less traumatic closure of the surgical flap. In general, the operator is working with relatively healthy tissue and no attempt should be made to remove or alter the periodontium. This is especially applicable when making a full sulcular flap.

All flaps are full thickness and the incision must be complete, so that there is no inadvertent tearing upon retraction of the flap. The split thickness flap is to be avoided, as it is the most traumatic and healing is compromised. The periosteum does not survive the flap reflection procedure. It has been postulated that depolymerised periosteal collagen plays a role in rapid reattachment of the flapped tissues to cortical bone.

In general, all flaps should be extended, at a minimum, to the
mesial of the second tooth anterior to the apex of the root being surgerised. The flap design differs depending on the integrity of the bone over the roots, the amount and nature of the attached gingival tissue, the anatomy of the jaw, and the presence or absence of fixed dental appliances. There are two flap designs: triangular (one releasing incision) and rectangular (two releasing incisions). They are normally either a full sulcular flap or a muco-gingival flap, depending on the location and situation presented to itself by the operator. In general, the longer the length of the flap, the easier it is to control and has no effect on the healing process.

The full sulcular flap
This design is routinely used in all posterior quadrants. The full sulcular flap should be used in the anterior if there is a zone of attached gingival tissue, or there is a concern about the possibility of a dehiscence over the root of the tooth being operated on. The incision is made through the gingival crest, following the curve of the teeth involved in the surgical area (Fig. 1). The operator should attempt to incise the tissue through the gingival crest to the osseous crest of bone, leaving the healthy gingival attachment intact (Fig. 2). The advantage of the full sulcular flap is the ability of the operator to visualise the emergence form of the involved teeth easily.

The Leubke-Ochsenbein or muco-gingival flap
This flap is used only when there is an adequate amount of attached gingival tissue present and the periodontal probing is within normal limits. The incision design should be scalloping in nature and generally follow the architecture of the teeth, which allows for easy repositioning upon completion of the apical microsurgical procedures (Fig. 5).

All releasing incisions are made parallel to the long axis of the teeth. This is important because the blood supply to the area is also parallel to the long axis. If a wide-based flap is made, the blood supply to the tissue adjacent to the flap will be compromised and healing may not be as predictable or uneventful.

The reflection of the flap is accomplished using either the Molt, Ruddle II, or Ruddle 1, (SybronEndo) periosteal elevators. The working end of the instrument is gently inserted into the releasing incision, line into the free gingival tissue apical to the muco-gingival attachment and as far apically as the incision and bony contours will gently permit (Fig. 4). The instrument is manipulated in a gentle up-and-down (apical-to-coronal) movement within the unattached gingival portion of the flap. Maintaining the same motion, the instrument is moved slowly towards the same apical position at the more distal extent of the flap. The working end of the elevator should be sharp so that the reflection will be a dissecting process, thus crushing or tearing of the tissue is avoided.

Occasionally, especially in the posterior quadrants of the mandible, the muco-gingival line will actually be attached to a microscopic bony ridge. The attached tissue must be gently dissected from it. Once the mesial few millimetres are loosened, the rest will generally peel away without much effort at all and will gently release from the osseous surface. The time spent initially to gently free the attached gingiva will be rewarded by a healing process that is more likely to be uneventful.

This atraumatic elevation and reflection of the flap is a major contributor to the rapid healing response routinely observed only 24 hours post-operatively. It is important that the approximating surfaces of the flap are not touched after the incision is completed, so that there are no crushing injuries to inhibit or retard the healing process. An instrument such as the old wax apatula-shaped periosteal elevator has no place in the armamentarium of the endodontic microsurgeon.

Once the flap is gently and cleanly reflected, any tissue tags should be left intact as they will aid in the healing process. It’s not necessary to clean the flap and exposed bone, as these efforts are time-consuming, can be traumatic to both the hard and soft tissues, and ultimately compromise the healing process.

The retraction of the flap must also be accomplished in a gentle and atraumatic manner. The most common cause of post-operative pain and swelling arises from impingement of the tissue during the retraction process (Fig. 5). The operator has to modify the end of the retractor constantly to ensure there is no inadvertent impingement on the flap. This is when the ‘scope’ assistant is most helpful because they are observing the surgical site with a different set of eyes.

An effective way to achieve atraumatic retraction is to prepare a groove in the cortical plate of the bone, well apical to the anticipated access to the root end. A surgical length #8 round bur, on a high speed Innovator hand-piece (SybronEndo), is used to make the groove. A high-speed handpiece that has air escaping from the working end should never be used because of the danger of air embolism.

The groove creates a definite place for the retractor instrument to seat into, which can then be easily maintained in position, by either the doctor or the assistant, thereby eliminating the problem of inadvertently slipping during the surgery. Impingement of the tissue is also more predictably avoided by using a groove to hold the retractor.

Retraction can be accomplished using either the Carr or Rubinstein Retractors. However, there are many different styles of retractors from which to choose. The specific retractor chosen is the one that will best maintain clear visibility to the surgical area and be comfortable for the operator to hold during the surgical procedure (Fig. 6).

After the flap is retracted and if there is any tension on the flap, the vertical releasing incision can be extended, or an additional releasing incision at the opposite side of the flap can be considered. The releasing incision is usually minimal, only three-four mm long, and often does not require suturing. In any case, it is imperative that the operator keeps in mind there should be no tension or stretching of the tissues. One should not hesitate to extend or modify the incision, to eliminate tension on the tissues during retraction. When there is tension, there is usually an opportunity for crushing or ischaemia of the tissue and a resultant delay in the healing process. Generally speaking, the less the tension the easier it is to maintain atraumatically during the surgical procedure.

About the author
Dr John J. Stropko received his DDS from Indiana University in 1984 and for 24 years practised restorative dentistry. In 1989, he received a certificate for endodontics from Boston University. He recently retired from the private practice of endodontics in Scotlanddale in Arizona. Dr Stropko is an internationally known speaker. He has been a visiting clinical instructor at the Pacific Endodontic Research Foundation (PERF), an Adjunct Assistant Professor at Boston University and an Assistant Professor of graduate Clinical Endodontics at Loma Linda University. His research on vivo root canal morphology has been published in the Journal of Endodontics. He is the inventor of the Stropko Irrigator, which has published in several journals and textbooks, and is an internationally known speaker. Dr Stropko has performed numerous live micro-endodontic and micro-surgical demonstrations. He is the co-founder of Clinical Endodontic Seminars.
