Replacement of teeth through implantation and ridge expansion

A case report

Authors: Carlos Barrado & Juan M. Ambros, Spain

**Introduction**

The use of implants with a tapered design and a short drilling sequence is an increasingly common trend, since such implants allow us to perform simple, quick and minimally invasive surgery in the bone. Working with an implant system that has a short drilling sequence also allows us to use a simple and ergonomic surgical tray, which facilitates the work of the surgeon and support staff (Fig. 1).

Moreover, the use of threaded osteotomes is a simple, predictable surgical technique that allows the dentist not only to place implants in areas with a narrow transverse diameter without bone regeneration, but also to improve bone quality in the receiving area and to reduce the drilling sequence in cases of immediate post-extraction implantation.

In the clinical case presented here, transverse bone volume was needed to place two implants in...

positions 25 and 26. Instead of guided bone regeneration with an autogenous bone block or xeno-
geneic bone substitute material covered with a collagen membrane, a crestal expansion with
threaded osteotomes was proposed. Also, it was decided to use BEGO Semados RSX implants (BEGO
Implant Systems) because of their macroscopic tapered design and high self-tapping property.

Clinical case

A 60-year-old non-smoking female patient without any noteworthy clinical pathology or cur-
cent drug treatment came to our clinic reporting pain and swelling in tooth 27, which was a support-
ing element of a bridge on teeth 24–27 (Fig. 2). A root fracture with a large apical cyst affecting
the three roots of the molar was observed on a CBCT scan (Fig. 3). Based on this finding, the fol-
lowing treatment plan was proposed to the pa-
tient:

1) extraction of tooth 27 with cyst removal;
2) bone regeneration of the area using a xenograft particulate bone substitute material (BEGO OSS,
BEGO Implant Systems), covered with a resorbable collagen membrane (BEGO Collagen
Membrane, BEGO Implant Systems);
3) replacement of teeth 25 and 26 using two implants (BEGO Semados RSX) and bone expan-
sion;
4) seating of a full lithium disilicate ceramic crown (IPS e.max, Ivoclar Vivadent) on tooth 24 fabri-
cated with the CEREC system (Sirona Dental) in the clinic on the same day of the surgery;
5) seating of full lithium disilicate ceramic crowns (also IPS e.max) on the implants placed in re-

gions 25 and 26 three months after the surgery.

After removal of the old fixed prosthesis, and before starting the surgery, tooth 24 was prepared
(Fig. 4) and a digital image captured (Fig. 5). Thus, the lithium disilicate ceramic crown could be de-
signed and fabricated with the CEREC system while the implant surgery was performed. Finally, the
crown could be cemented at the end of surgery. In order to start the surgery, a full-thickness mu-
coperiosteal flap with a mesial vent for papilla preservation was raised (Figs. 6–8).

Threaded osteotomes were used after the initial drilling (Figs. 9–11), taking into account the trans-
verse bone loss that existed in the area, as well as the emergence profile of the implant and the fu-
ture prosthesis. This step had two aims: good 3-D location of the implant and bone condensation,
which would improve the bone quality in the re-

cieving area (Fig. 12).

For this clinical case, it was necessary to use an implant that could be easily and atraumatically in-
serted in order to prevent a greenstick fracture of the buccal cortical wall. Owing to their tapered body design and high self-tapping property, two BEGO Semados RSX implants were selected (Figs. 13–15). This implant was also selected because of
