Endodontic management of a hypertaurodontic maxillary first molar—
A case report with a two-year follow-up

Authors: Drs Jojo Kottoor, Denzil Valerian Albuquerque, Anuj Bhardwaj, Sonal Dham & Natanasabapathy Velmurugan, India

**Introduction**

Taurodontism is a morphological variation in which the body of the tooth is enlarged and the roots are reduced in size. Taurodontic teeth have large pulp chambers and apically positioned furcation. This variation was first described by Gorjanović-Kramberger; however, the term “taurodontism” was first introduced by Sir Arthur Keith to describe molar teeth resembling those of ungulates, particularly bulls. The term “taurodontism” comes from the Latin term “tauros”, which means “bull” and the Greek term “odus”, which means “tooth” or “bull tooth”. Such morphological variations are an endodontic challenge and even more difficult to treat when additional roots and/or canals are present. The endodontic management of one such taurodontic molar is reported in this case report.

**Case report**

A 44-year-old male patient was referred to our clinic for treatment of the right maxillary first molar (tooth #16). The preoperative periapical radiograph (Fig. 1a) suggested the following possibilities:

- a mesio-occlusal carious lesion with endodontic involvement;
- a highly calcified and elongated pulp chamber extending up to the trifurcation;
- three short roots with the trifurcation in the apical third; or
- a periapical radiolucency in relation to the mesio-buccal and palatal root apex.

Clinically, vitality tests were negative and a diagnosis of hypertaurodontism, according to Shifman and Chananel, with pulpal necrosis was made for tooth #16 and endodontic treatment was planned.

Local anaesthesia of 2% lidocaine with 1:100,000 epinephrine was administered to the patient. The mesial surface of the tooth was restored with composite resin (Z100, 3M ESPE) after caries excavation to enable optimal isolation. Under rubber dam...
tion, the access cavity was established with an Endo Access bur and an Endo Z bur (DENTSPLY Tulsa). A dental operating microscope (DOM; Seiler Revelation) was used throughout the procedure to facilitate visualisation. The calcified mass occluding the pulp chamber was removed using ET 18D ultrasonic tips (Satelec/Acceleon). Three root-canal orifices were located: two narrow orifices, the mesiobuccal and distobuccal, and a wide palatal orifice. Root-canal orifices were named according to the nomenclature proposed by Kottoor et al. An electronic apex locator (Root ZX, Morita) was used to determine the initial working length, which was confirmed radiographically (Fig. 1b). The root canals were cleaned and shaped with ProTaper (DENTSPLY Maillefer) rotary instruments. The buccal canals were instrumented up to F2 and palatal canal to F4. The canals were irrigated with 2.5% sodium hypochlorite using ultrasonics, 17% aqueous solution of EDTA, and 0.2% w/v chlorhexidine gluconate. The canals were dried using sterile paper points and obturated with gutta-percha cones and AH Plus sealer (DENTSPLY DeTrey) using the cold lateral compaction and vertical compaction techniques. The access cavity was then restored with miracle mix (cermint and Ketac Silver, 3M ESPE; Fig. 1c).

The patient returned to the endodontic clinic after three weeks with sensitivity in the same tooth on consumption of cold foods. The longevity of the complaint prompted a re-entry into the tooth to evaluate the possibility of any additional canal/s. The coronal restoration was removed and the pulpal floor was carefully inspected again under the DOM at a higher magnification. The visual and tactile examination under the DOM revealed a second mesiobuccal canal (P-MB). Under the microscope, it was possible to insert a #15 K-file and the existence of the additional canal was confirmed using an electronic apex locator. A working length radiograph was taken with a #20 K-file in the untreated canal (Fig. 1d). The P-MB canal was instrumented to F2 under irrigation with 3% sodium hypochlorite and EDTA and obturated by cold lateral compaction of the gutta-percha and AH Plus sealer (Fig. 1e). Follow-up clinical examination after a week revealed that the tooth was asymptomatic and was not sensitive to percussion or palpation. Subsequently, endodontic management of tooth #15 was completed. The 24-month follow-up radiograph showed complete resolution of the periapical radiolucency in relation to the mesiobuccal and palatal root apices (Fig. 1f).

**Discussion**

Taurodontism is frequently associated with other anomalies and syndromes. These include Klinefelter syndrome, ectodermal alterations, Down syndrome, Mohr syndrome, Wolf-Hirschhorn syndrome, Lowe syndrome, Tricho-dento-osseous syndrome, Williams syndrome, and Seckel syndrome, but it is not a constant feature of these syndromes. However, identification of patients with multiple taurodontic teeth could lead to early recognition of a systemic disorder and improve quality of life. It has also been found to be associated with dental anomalies such as oligodontia, supernumerary teeth, and amelogenesis imperfecta. In this case, the patient was a healthy male with a negative medical history.
Its aetiology is still unknown, but it has been suggested that it may be caused by a failure of the diaphragm of Hertwig’s epithelial root sheath to invaginate at the correct time and horizontal level or changes in the mitotic activity of cells of the developing teeth that can affect root formation or influence by external factors on the development of the teeth. Differences in opinion exist regarding the amount of displacement and/or morphological change required to constitute taurodontism. Based on the relative amount of apical displacement of the pulp chamber floor, Shaw classified taurodontism as hypotaurodontism, mesotaurodontism, and hypertaurodontism. This subjective, arbitrary classification led normal teeth to be misdiagnosed as taurodontism. Feichtinger and Rossiwal state that the distance from the bifurcation or trifurcation of the root to the cemento-enamel junction should be greater than the occluso-cervical distance for a taurodontic tooth. Keene proposed the Taurodont Index, relating the height of the pulp chamber to the length of the longest root. Although there are many classification systems to determine the severity of taurodontism, the classification proposed by Shifman and Chanannel in 1978 is the most widely used system. According to this index, taurodontism is present if the distance from the lowest point at the occlusal end of the pulp chamber to the highest point at the apical end of the chamber, divided by the distance from the occlusal end of the pulp chamber to the apex and multiplied by 100 is 20 or above (hypotaurodontism: TI 20–30; mesotaurodontism: TI 30–40; hypertaurodontism: TI 40–75).

Except for a higher prevalence of taurodontism among females in a Chinese sample, no study has found a gender difference for this abnormality. Although permanent mandibular molars are most commonly affected, taurodontism is occasionally observed in mandibular premolars and even in maxillary premolars, mandibular canines, and incisors. Its prevalence has been reported as ranging from 5.67 to 60% of subjects. In a recent study, it accounted for 18% of all anomalies.

Endodontic treatment in taurodontic teeth has been described as complex and challenging because the apical position of the pulpal floor can make it difficult to identify and locate root-canal orifices. In the present case, an apical third trifurcation with four root canals was observed. The mesiobuccal and distobuccal canal orifices were very narrow and close to each other, which made identification and negotiation of these orifices very difficult. Additionally, the proximity of the orifices and deeply situated opening of the canals made it difficult to identify the P-MB during the initial visit. However, during the second visit, the use of DOM enhanced the visualisation of the pulpal floor by better illumination of the depths of the cavity. Hence, success was largely dependent on the use of magnification, which allowed for the identification of the P-MB canal with ease. During instrumentation, the shortened length of these canals allowed for instrumentation with only the apical third of the file, also making it time consuming. Thus, endodontic treatment of taurodontic teeth may be complex, particularly regarding the cleaning and shaping of the root canals and root-canal obturation, especially in hypertaurodontic teeth.

**Conclusion**

The case report has described the successful endodontic treatment of a hypertaurodontic maxillary first molar that would have seemed impossible to perform with conventional techniques. Success was mostly attributed to the use of magnification, which allowed better visualisation of the four canal orifices. This case report has served to illustrate to clinicians that sound knowledge and modern equipment facilitate enhanced management of endodontically challenging taurodontic teeth.
